FORD MOTOR COMPANY—WIXOM ASSEMBLY PLANT

In June and July of 1987, the Hydrogeologic Section of the Environmental Response Division (ERD), Michigan Department of Natural Resources (MDNR), responded to a request by the Detroit District Environmental Response Division staff to participate in a field investigation at Ford Motor Company's Wixom Assembly Plant. In mid 1986, drums containing hazardous materials were uncovered during construction of an on-site wastewater treatment facility and raised concerns about reports that other hazardous materials were buried within the plant property.

The purpose of the investigation was to confirm the presence of purported buried wastes by (1) identifying their location(s) through the use of geophysical methods and correlation borings, (2) by collecting and analyzing soil samples of questionable materials, and (3) by collecting and analyzing groundwater samples to determine whether hazardous materials were causing groundwater contamination.

A field visit to the plant was made by MDNR personnel in June of 1987 to evaluate site conditions as they related to the goals of the investigation. The area was inspected for locations of overhead and underground utilities, buildings, roads, lagoons, surface topography, etc. The site (Figure 1; 2 sheets) was divided into three separate areas, each having a specific investigative goal.

Site #1 consists of a landfill of approximately 25 acres in size. In this area, the goal was to determine whether local groundwater quality was impacted by the landfill. This was accomplished by installing several monitor wells at specific depths and locations, as necessary, around the perimeter of the landfill. Groundwater was sampled from these wells by District staff and analyzed for selected parameters by the MDNR Environmental Laboratory.

Site #2 consists of a rectangular area approximately 1000 feet x 400 feet. In site #2, an EM survey was conducted throughout the area to define sites of anomalous electrical conductivities. These anomalous areas, contrasting with background conductivities, were further investigated by collecting continuous split spoon core samples from the ground surface to an unaffected depth. Questionable materials collected during the sampling process were analyzed by the MDNR Environmental Laboratory for selected parameters. If a saturated zone was encountered during the sampling, a temporary well would be installed to collect a water sample for analysis by the laboratory.

Site #3 consists of a triangular area approximately 300 feet x 350 feet x 150 feet. During construction of footings for an overhead trestle system, questionable sludge materials were uncovered. An intensive soil boring and split spoon sampling program will be conducted to define the horizontal and vertical extent of the sludges. If a saturated zone was encountered during the sampling, a temporary well would be installed to collect a water sample for analysis.

GEOLOGY

Wixom is situated in a diverse geologic setting. The surface and near surface features are a result of several periods of glaciation, most likely the result of the most recent which ended approximately 10,000 years ago. Many landforms are located in the area, ranging from lakes and swamps to level plains and rolling hills. All types of soils exist, from sands and gravels to clays and mucks. As can be seen by a review of a glacial geologic map of the area (Figure 2), the Wixom area lies in a outwash channel directly west of two parallel morainal ridge formations. These moraines represent the margins of glacial ice and are composed of medium to coarse grained sands, gravels, clays, and loams randomly deposited when glacial ice was at a standstill. Between these ridges and directly adjacent to them are outwash deposits consisting of stratified sands, silts, and gravels. These deposits were created as a result of sedimentation from soil laden glacial melt waters.

FIGURE 2

3

--- DENOTES GLACIAL OUTWASH DEPOSITS
(i.e., stratified sands, gravels, etc.)

--- DENOTES GLACIAL MORAINAL DEPOSITS
(i.e., unstratified clays, loams, etc.)

Specifically, the Ford Assembly plant is situated on both outwash and morainal deposits. Near surface soils consist of clays, silts, loams, sands, and gravels, and combinations of some or all of the above. Most of the outwash deposits occur in layers ranging from a few inches to a few feet in thickness. Not all layers are continuous throughout the area and may not even exist in others. The morainal materials are randomly deposited and exhibit no specific vertical or horizontal features. The combination of outwash and morainal deposits in the plant area contribute to complex groundwater flow patterns.

INVESTIGATION--SITE #1

In Site #1, a total of 9 wells were installed (Figure 1). Previous studies conducted within the plant property indicated a north-northwesterly groundwater flow direction. Assuming this information is correct, three to four of the wells can be considered upgradient of the landfill and the remainder as downgradient. All wells were screened in saturated zones as determined by drilling to an approximate depth of 25-30 feet. Three of these upgradient wells are located immediately southeast of the fill, and the fourth well is located west-southwest of the fill. All of these wells were completed with the screen section in the saturated zone nearest the ground surface. None of the wells were developed with the exception of monitor well #1.

All drill cuttings were placed in 55 gallon drums provided by Ford Motor Company pending hazardous waste characterization, with the exception of monitor well #1. This well was completed and developed prior to the request to drum all drill cuttings and fluids. Characterization of materials for the presence of hazardous materials would determine the methods of dealing with borehole materials and future development waters.

A total of five wells were installed at four locations downgradient from the landfill. These wells were located along the north and northwestern sides of the landfill. Each well was completed in the saturated zone nearest the ground surface with the exception of monitor well #4D. This well was screened in a lower zone of saturation to establish a sampling point for monitoring groundwater quality in the lower zone.

Care was taken to prevent any connection between saturated zones in the event that either one or all were contaminated. This was accomplished by grouting the entire length of the borehole except in the immediate vicinity of the screened interval. Grouting consisted of pumping an expansive bentonite slurry down the borehole through the center of the in-hole hollow stem augers. As the level of the grout was elevated to the surface, augers were pulled from the borehole, permitting the bentonite slurry to flow into the borehole from the bottom of the augers. This insured an effective seal between different zones within the borehole. A cemented zone at the top of each borehole provided a seal against any surface induced contaminant from entering the borehole. Each well was equipped with a locking vented cap for security. See Appendix B for individual well logs.

All augering equipment was thoroughly steam cleaned prior to use and after each installation to prevent any contamination or cross contamination from impacting the wells.

All the monitor wells were vertically gamma ray logged. Gamma ray logging is a borehole geophysical technique used in interpreting the vertical lithologic distribution of soils in the immediate vicinity of the borehole. Gamma ray logging measures the total amount of naturally occurring gamma radiation, in counts per second, within soils caused by the presence of uranium, thorium, and potassium. Generally, clay and silt materials, which act as hydrologic barriers, are more radioactive than sands and gravels.

Gamma logging is conducted by lowering and raising a cylindrical gamma radiation measuring probe inside the well. The instrument is calibrated, with respect to the total range of radioactivity present, as it is lowered into the well and a record of the hole collected as the probe is elevated at a specific rate of speed.

INVESTIGATION-SITE #2

In site #2, an electromagnetic (EM) conductivity survey utilizing a Geonics EM-31 instrument was conducted by DNR geologist Kevin Kincare. Sharon A. Mason, Ford Motor Company hydrogeologist, assisted in this survey.

The EM-31 is a geophysical instrument which utilizes two electrical coils to induce and measure an electromagnetic field. A transmitter coil induces an electromagnetic field into the ground and a receiver coil measures the resultant current field which is directly proportional to the ground conductivity. This instrument is useful in delineating areas of buried metallic objects or extraneous fluids having conductivities contrasting with background levels. This instrument has a fixed intercoil spacing of 3.7 meters for an effective depth of exploration of approximately 6 meters.

Ground conductivity is dependant on the ionization characteristics of the soil. It is also dependant on the fluid content and type. For instance, quartz sand has few unsatisfied electrical bonding sites in its chemical structure and, therefore, exhibits low conductivity. Clay minerals have net electrical charges (many bonding sites) and resultant high conductivities. Water with low levels of dissolved solids have few ions in solution, a low ionization potential, and low conductivities. Increasing the amount of dissolved solids, therefore, increases the conductivity. Metals are characterized as having shared electrons that are easily ionized and as such, metals, especially ferrous metals, have very high conductivities.

For this survey, a point at the extreme northern end of the plant property--X-1525, Y-2475--was chosen for calibrating the EM-31. This point and the surrounding area north of the ditch had a relatively uniform conductivity of 13 μ mhos/meter.

The total area which could be effectively surveyed within site #2 was somewhat limited by the presence of metallic construction materials (cultural interferences) stored about the site. However, several clear lines were surveyed. Refer to Figure 1 for locations of the EM data points.

Two areas were discovered, one having conductivity values approximately twice as high as background and another having values approximately 10-15 times background. These areas were cored by the split spoon method and samples collected for analysis when questionable materials were encountered. Additional borings were conducted in background areas for the purpose of correlation to the EM survey.

INVESTIGATION-SITE #3

In site #3, a total of 10 borings were conducted (Figure 1). Each boring was conducted by progressively advancing a two foot split spoon sampler ahead of the auger string. Continuous samples were collected at two foot intervals from the surface to an unaffected depth. When questionable materials or saturated zones in the immediate vicinity of the questionable material were encountered, a sample was collected for laboratory analysis. Each boring was either backfilled with a expansive bentonite slurry or with the borehole cuttings depending on the geologic conditions present. See Appendix C for individual boring logs.

INVESTIGATION RESULTS

In site #1, the three upgradient wells depict a multi-layered pattern. This pattern consists of a brown to grey loamy clay layer from the surface to approximately 3 feet below grade. From 3-7 feet, there are sands & loams, from 7-12 feet are clays & loams, from 12-15 feet are sandy zones, from 15-25 feet are loams & clays, and from 25 feet to the

bottom of the borehole are predominantly sands & gravels with substantially less clays than the above layers. The extent, depths, and thicknesses of these layers vary from well to well. The remaining monitor wells downgradient of the landfill also depict a multi-layered pattern. This pattern consists of a fairly thick (3-5 feet) layer of black top soil overlying a 4 feet thick saturated grey silt to sand layer. These layers are above a 10-12 feet thick brown and grey silty clay layer having a minor (1-2 feet) thick silty sand layer within it. This silty sand layer in some instances is saturated. Below this are saturated silty grey sand and gravel layers (20-27 feet below grade) interbedded with thin (less than 1 foot) layers of silty clay.

The silty clay layers from approximately 9-20 feet below grade appear to diminish in thickness and lateral extent to the west. In monitor wells #5 & #7, the layers are less predominant and are replaced by more sand and gravel materials.

Generally, it could be inferred that a similar multi-layered pattern existed in the landfill area. Prior to its existence, the area was likely as follows: from the surface to an approximate depth of 5 feet was top soil, from 5 feet to approximately 10 feet was a sand and gravel layer, from 10 feet to approximately 21 feet was a silty clay layer interbedded with minor sand lenses, from 21 feet to 25 was saturated silty sands and gravels, and from 25 feet-? was silty clays.

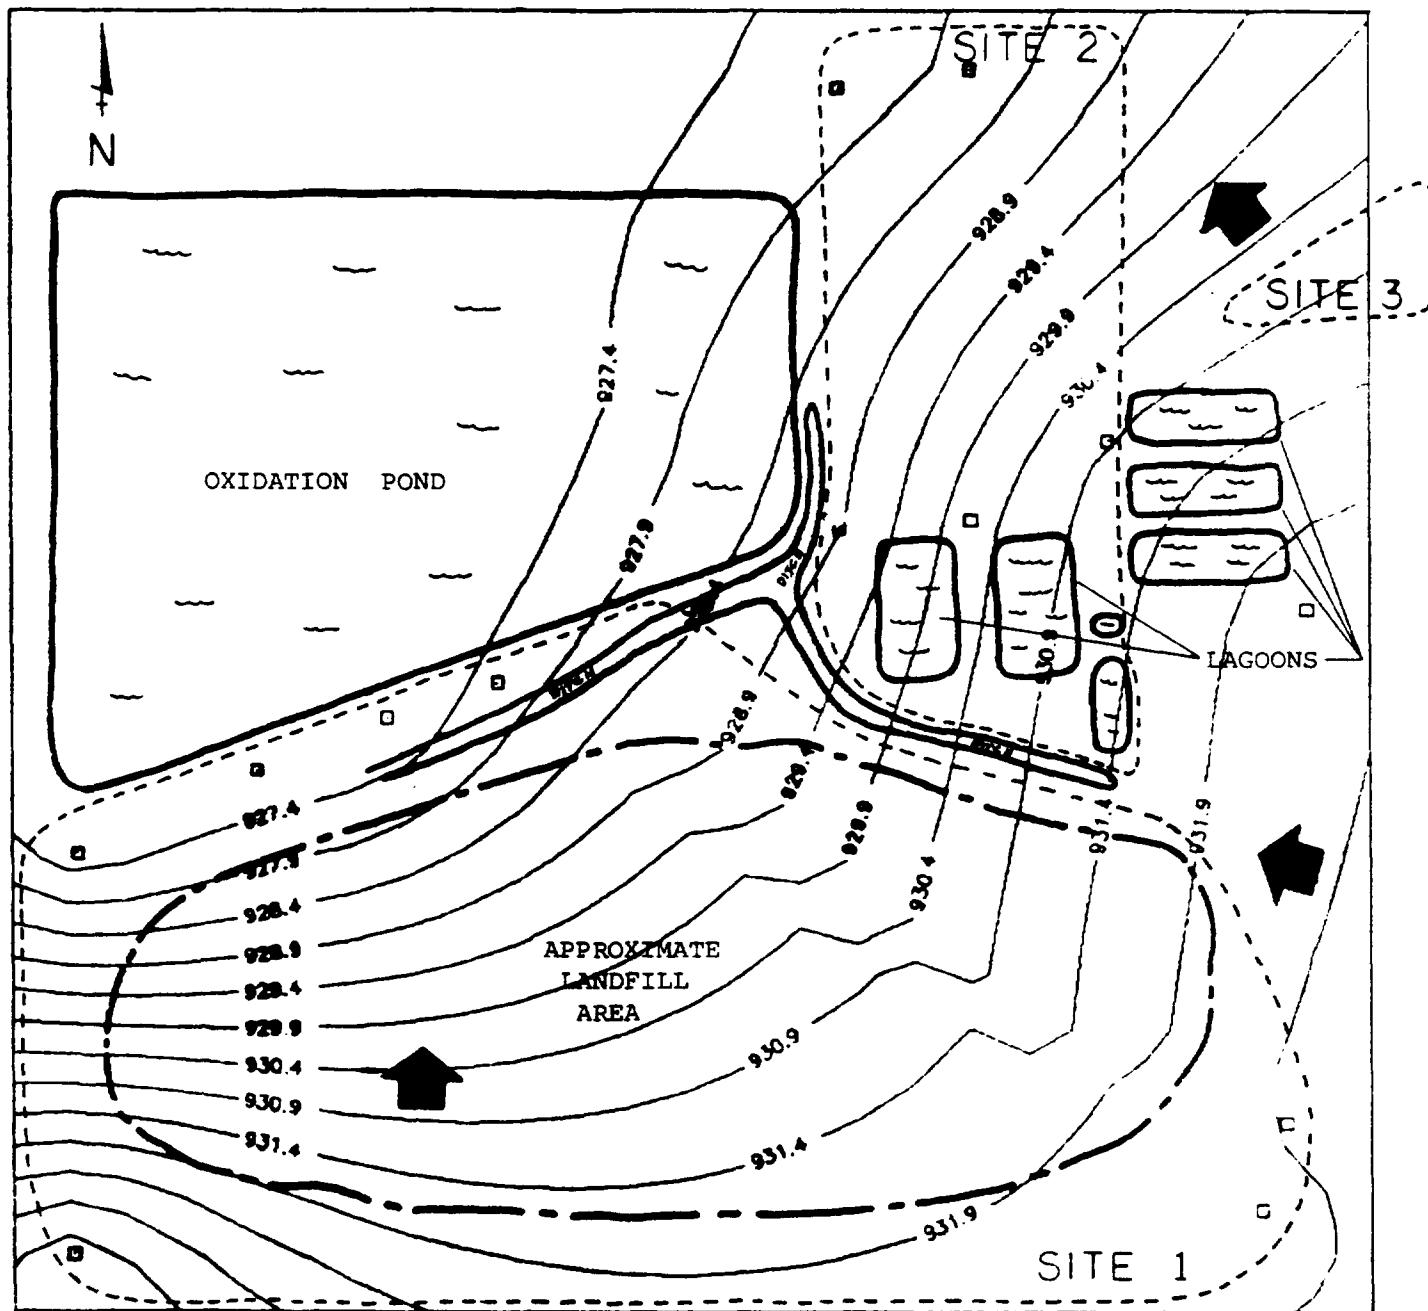

Because of the potential hazards, no drilling was conducted within the landfill. Therefore, no positive connection or correlation of layers was determined. Certainly, the upper 5-10 feet of soil has been disturbed by the landfill operations. The lower sand and gravel layers may be acting as possible conduits to fluid movement, depending on the depth of the landfill cut and the lateral and vertical extent of the clay deposits.

After all monitor wells were installed and allowed to equilibrate, a static water elevation was measured in each well. Comparison of the static water elevations to the geologic cross-sections indicate confined aquifer conditions and, therefore, the elevations are indicative of a piezometric surface as compared to a water table surface. This data was used to determine the piezometric surface configuration for the area and a contour map (Figure 3) prepared which graphically shows the surface and the local groundwater flow direction. Analysis of the map indicates that groundwater is flowing in a north to northwest direction depending on location and confirms the flow direction determined from previous studies. There does not appear to be any groundwater mounding in the vicinity of the landfill which could infer its geologic isolation from the surrounding area.

In site #2, the electromagnetic (EM) survey was conducted in all areas where no cultural interferences existed (Figure 1) and a statistical analysis of the data performed. From a total of 821 points, the highest value was 140 mmhos/m and the lowest point was 0.7 mmhos/m. The sample mean was 33 mmhos/m with a mode of 19 mmhos/m which indicates an uneven distribution. Sample skewness of 1.3 indicates a strong imbalance toward lower values. The kurtosis value of 3.8 shows an extreme degree of clustering of data values around the mean. The standard deviation of the sample population is 28. Values above 100 mmhos/m are, therefore, 2.39 standard deviations from the mean. There is a 98% chance that values greater than 100 mmhos/m are anomalous.

The majority of survey lines indicated no electromagnetic anomalies and had values ranging from 10-20 mmhos/meter. Three measurements of sludges generated at the plant were taken in the dewatered half of an oxidation pond on site to determine if they might have any impact on ground conductivities. Two measurements of 11 mmhos/m and one measurement of 12 mmhos/m indicate that the sludges would not cause any electromagnetic anomalies. There is a strong anomaly, however, in the southeastern portion of the site. This anomaly extends radially about 20 feet from the point at X-1735, Y-1555. The highest measurement of conductivity (140 mmhos/m) occurred at X-1735, Y-1535 with 30 adjacent

FIGURE 3

PIEZOMETRIC SURFACE and GROUNDWATER FLOW DIRECTIONS

■ - DENOTES MONITOR WELL

← - DENOTES GROUNDWATER FLOW DIRECTION

points having values in excess of 100 mmhos/m. Two correlation soil borings (#12 & #13) were conducted in this area to determine the source of the anomaly. From approximately 1-5 feet below grade, a black greasy sand and gravel mixture containing melted metallic materials was found.

This material appears to be some type of foundry sand and is likely the cause of the anomalous EM readings because of its composition and proximity to the surface. Below this layer, clay deposits were found to an approximate depth of 10-11 feet. No borings within this anomalous area were extended below this depth. Soil boring #12 was abandoned by grouting the entire length of the borehole with an expansive bentonite slurry because of the saturated zone at 10-10.5 feet below grade. Soil boring #13 was abandoned by backfilling the hole with compacted borehole materials.

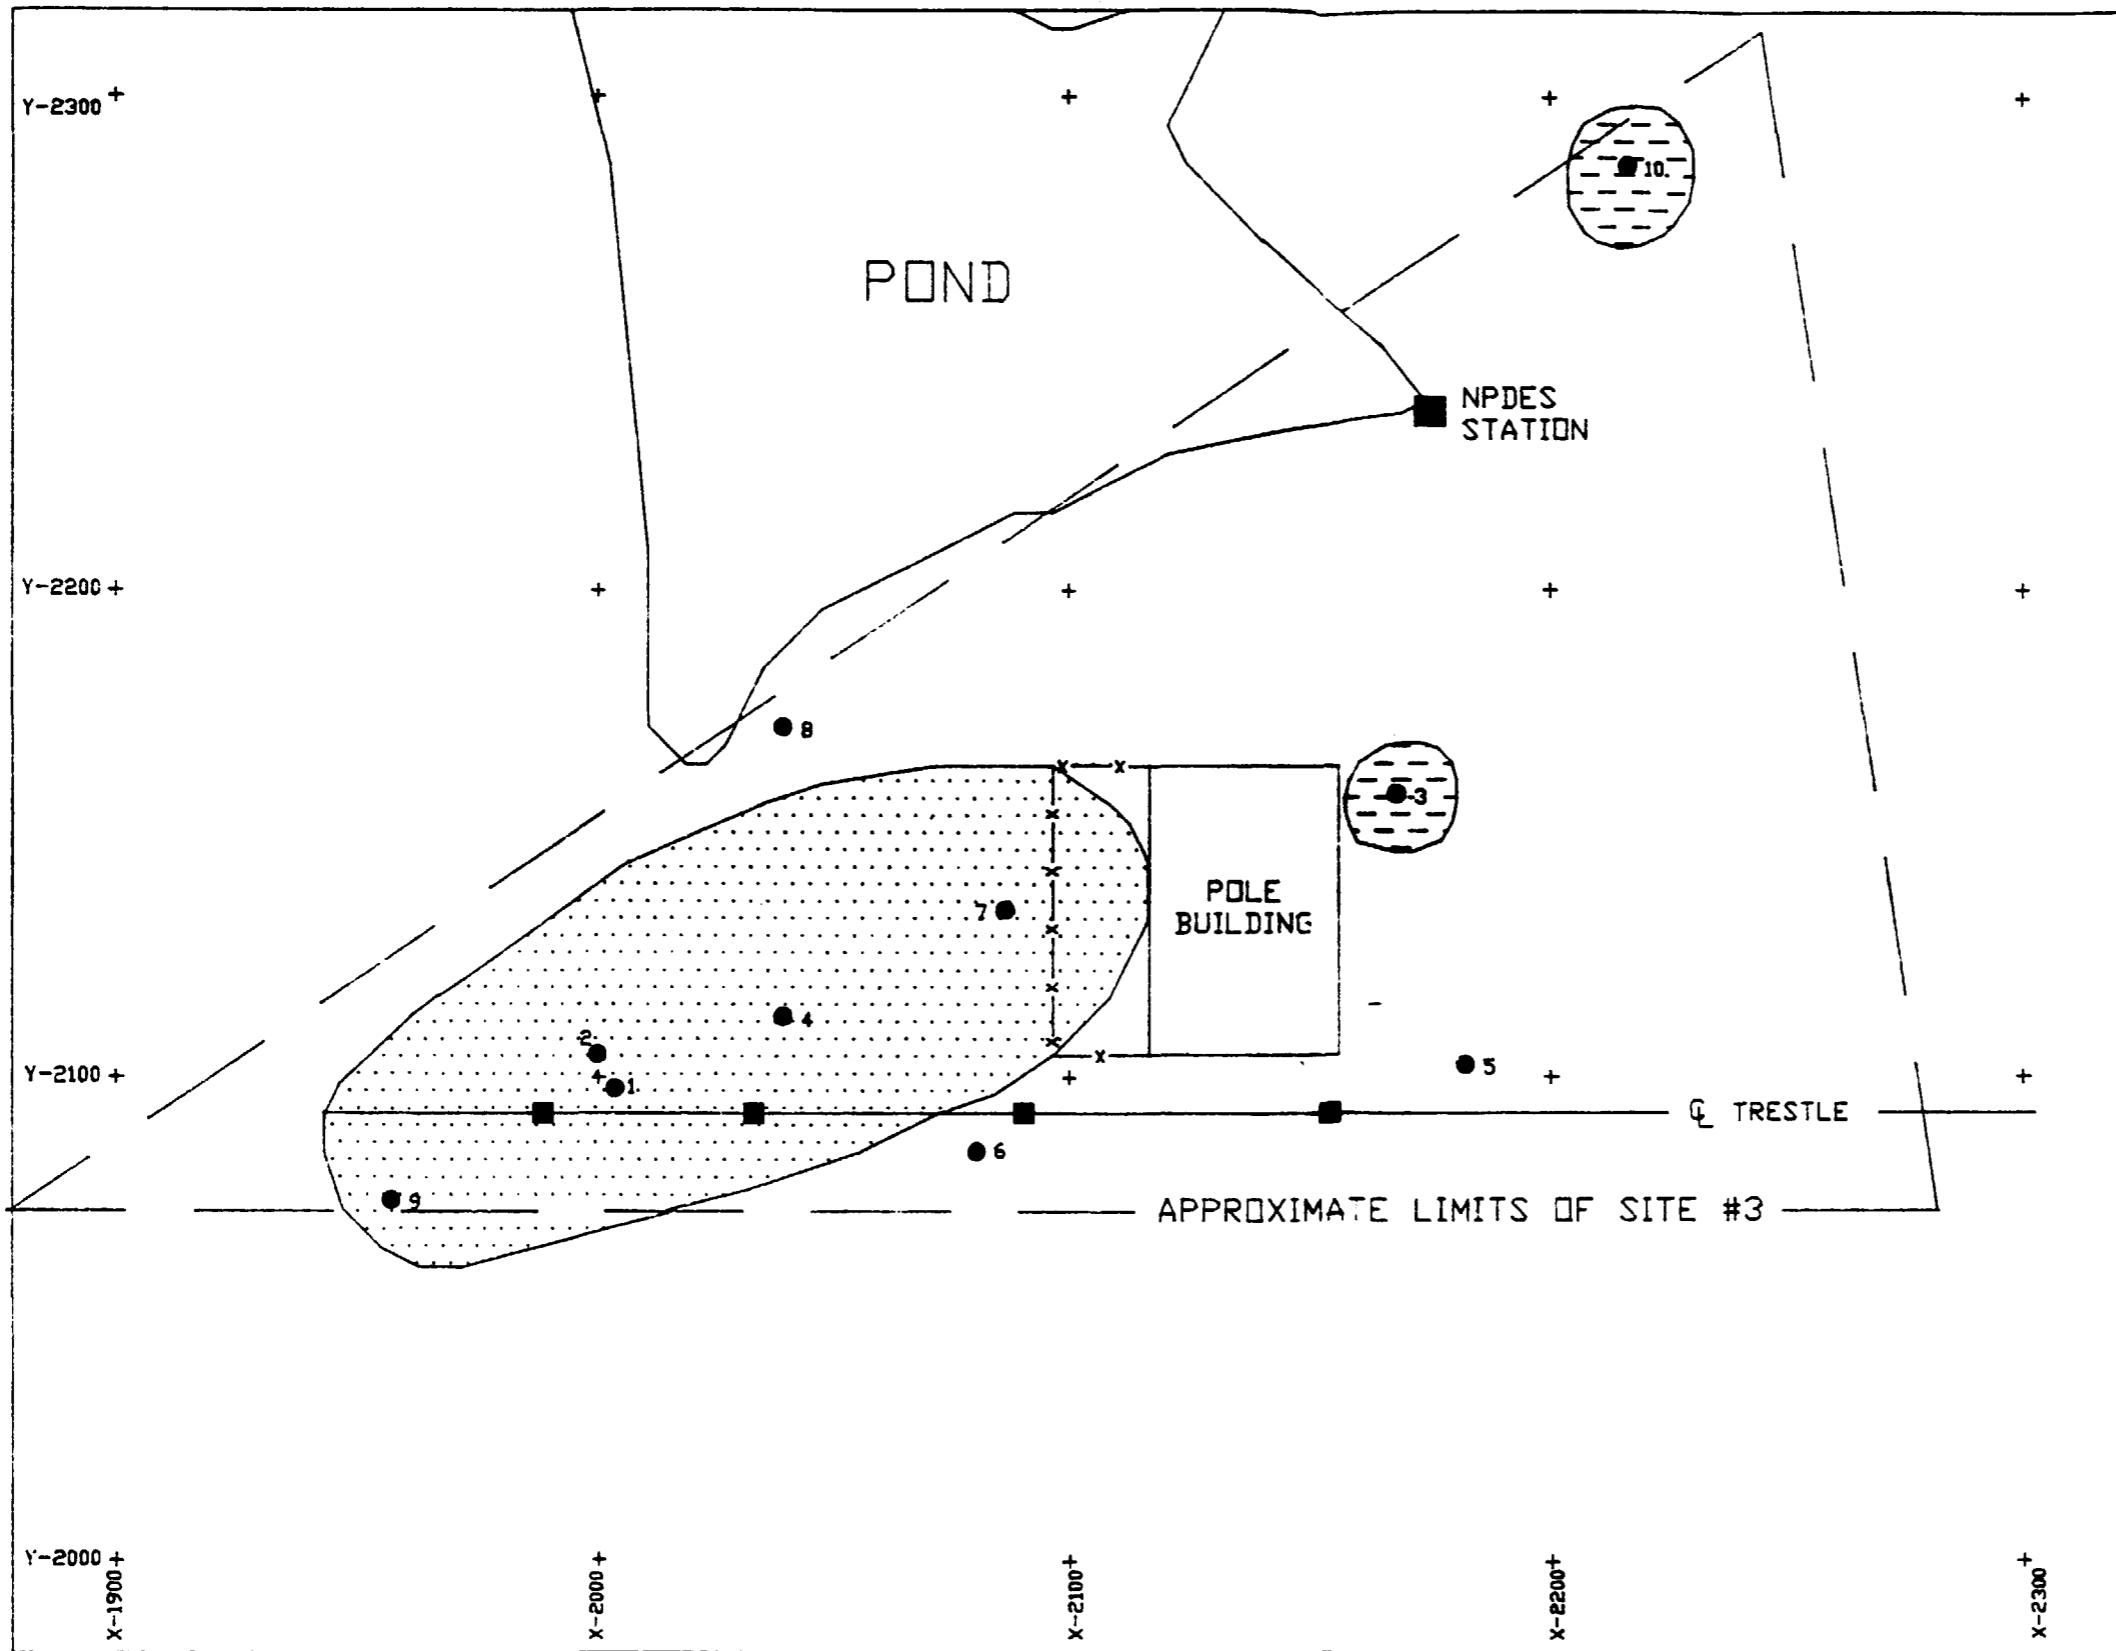

A correlation soil boring (#11) at station X-1745, Y-1940 was conducted in the area having EM values approximately double that of background. Three feet of gravel overlies clay deposits of at least 11 feet in thickness. No questionable materials were found in this boring. The borehole was abandoned by backfilling with compacted borehole materials. The slightly elevated EM values in this area are likely attributable to scattered scrap metal near the surface, the composition of the gravel, or to the amount and extent of clay found in the boring.

A correlation soil boring (#14) was conducted at the extreme northwestern corner of the plant property. In this boring, a soft red cohesive loamy layer was found from approximately 1-2 feet below grade. Below this layer was clay interbedded with thin (less than 1/2 feet thick) sand lenses. A sample of this red loamy material was collected for analysis and the borehole abandoned. A final correlation boring (#15) was conducted at X-1668, Y-2100, a randomly chosen location. This boring consisted of mostly silty clay deposits interbedded with thin lenses of clay loams. No questionable materials were discovered in this boring and the hole was abandoned.

In site #3, five of the ten borings revealed the presence of sludge materials. This sludge was black in color, had a tar-like consistency, and was found in a zone ranging from 4-7 feet in depth. In soil boring #7, the sludge was found from approximately 5-9.5 feet below grade. Several samples of this material were collected for laboratory analysis. In soil boring #2, the sludge had a sandy texture and was saturated. A temporary well was installed and a water sample collected from this boring.

Two of the remaining borings revealed the presence of black foundry-type sand and gravel. Melted metallic materials were present in these soils indicating a non-natural origin. Figure 4 is an enlargement from Figure 1 of the area where these sludges and questionable materials were found and delineates their approximate lateral extent.

In soil borings where the tar like substances were found, all questionable materials were stored in 55 gallons drums. All of the soil borings in site #3 were abandoned in a manner dependent on the geologic conditions present. If any saturated zones were encountered at any depth within the boring, the entire borehole was filled with an expansive bentonite slurry. If no saturated zones were encountered, the borehole was backfilled with compacted borehole materials. Throughout sites #2 & #3, all of the soil borings consisted of interbedded sand and clay deposits. The predominant soil was clay. It appears that these clays were both till and swamp deposits. The till clays were quite silty, dry, and contained a mixture of pebbles of varying sizes. The swamp deposits contained organically decaying roots and twigs and contained shells of simple organisms in a clay matrix.

IN SITE #3

On July 22 and 23, 1987, all of the monitor wells were sampled for analysis by the MDNR Environmental Laboratory and the Ford Motor Company laboratory. Each well was developed by the surge block method for a limited period of time. The amount of time that each well was developed was either (1) until a 55 gallon drum was filled, (2) until development water was clear, (3) or it was believed that the development water was representative of the aquifer zone in which it was screened. The development water from each well was collected into 55 gallon drums provided by Ford Motor Company, pending chemical analysis.

A complete listing of all samples collected and their locations is included in this report (Appendix A). All of the monitor well logs and gamma ray logs (Appendix B) and soil boring data (Appendix C) are included in this report. Actual EM field data is available on request.
